1 Introduction

1.1 Problem background

When performing a pentest on Windows Active Directory environments, one of the goals is usually to obtain Domain Administrator privileges in the form of a Domain Admin account. There are numerous ways to gain initial foothold in an Active Directory Domain, but the most common one is by exploiting the native protocols NetBIOS Name Resolution (NBNS) and Link-local Multicast Name resolution (LLMNR)[24] to gain crackable hashes which can be bruteforced offline. Hereafter a number of different techniques and exploits can be used to gain additional credentials, but it usually consists of dumping cached credentials on domain joined hosts in one way or another.

As one can easily figure out this is usually a manual job where many different tools are joined together to produce the right result. This usually means it is a trivial and easy job, which requires a lot of time that can be spent on more advanced tasks. This is often done with tools not written by the pentester themselves, which can pose a security risk as the tools can be backdoored or otherwise have security vulnerabilities.

During a pentest it is usually required to be as silent as possible and not trigger any alerts in any Intrusion Detection System (IDS), Security Information and Event Management (SIEM) or similar systems. The risk of using publicly available tools is therefore also that the tools are highly likely to be detected by Antivirus (AV) and will often trigger unwanted alerts.

Another issue of performing pentests is to document and remember the order of tasks that where done. A pentest usually concludes with a report where the necessary steps are explained to the customer, and this includes in what order tasks were done and which user credentials were used.

1.2 Problem brief

The purpose of this project is to determine whether a proper solution to the aforementioned problem can be found, and to analyze how such a tool can be developed. The problem is split in two, where the first goal is to gain an initial foothold and the second is to gain Domain Administrator privileges. To accomplish this the many techniques and methods will be discussed and evaluated in comparison to each other, and the most valid solution will be implemented in a piece of software that aims to be easy to use and contain a high level of traceability.

The developed piece of software must be able to be easy to use so that an incentive to use it instead of other tools is created. It should be constructed with AV evasion in mind, such that it will not be detected by AVs. Furthermore it must be designed with traceability in mind, such that a clear timeline can be constructed and documented.

1.3 Report structure

1.4 Pentesting Windows Domains

2 Initial foothold

In a Windows Active Directory Domain there are numerous ways of gaining an initial foothold. The following methods are the most used in modern penetration testing of Windows AD environments.

BRUTE User credential bruteforcing

SPRAY Password spraying

EXPL Exploiting known vulnerabilities on unpatched systems

CLEAR Clear text passwords stored on public shares

SPOOF NBNS and/or LLMNR spoofing

All of the above mentioned methods have their weaknesses and strengths, which should be taken into account when choosing the best method or methods to gain initial foothold in a domain. To make an educated guess of which method(s) to pursue further a comparison between the different methods is needed. Table 1 gives a comparison of the different methods, and shows which weaknesses and strengths each methods possess.

Strength	**BRUTE**	**SPRAY**	**EXPL**	**CLEAR**	**SPOOF**
Is it automatable?	+	+	-	-	+
Is it fast?	-	-	+	-	-
Account lockout issues?[12]	-	-	+	+	+
Communication with critical systems such as a DC?	-	-	+	+	+
Easy to detect?	-	-	+	+	+
Is it easy to do?	+	+	-	(+)[1]	+
Points	2	2	4	3.5	5

Table 1: Comparison of different methods to gain initial foothold in a Windows AD environment

All of the above mentioned methods are valid and are actively used in real life penetration tests. Table 1 scores each method according to their pros and cons, and here the reader can clearly see that spoofing NBNS and LLMNR is the most optimal way of gaining initial foothold. This corresponds with real life experience where the protocols are enabled by default[21] and not monitored

[1]This method can be very time consuming

correctly. It is important to mention that there exists a situation and place for every method, but the chosen method of spoofing is what will suit this project the best.
Now that a method has been chosen, section 2.1 will look further into how spoofing can be done in an automated way.

2.1 Spoofing

To understand how spoofing of LLMNR and NBNS works we first need to elaborate how spoofing can lead to a credential compromise. To do this we need to understand how name resolution works in Windows, regardless of the protocol used. Windows follows a sequence of steps in order to resolve a host name.[15] The steps are the following:

1. The client checks to see if the name queried is its own
2. The client searches local Hosts file
3. The client queries the DNS server
4. If enabled, Name resolution is done (LLMNR and NBNS)

This is illustrated on figure 1 where it is also illustrated how spoofing fits into the sequence. As it is shown, the Attacker will listen to multicast packets sent on the local subnet and answer to any Name Resolution packets. If successful, the *Client* will register *Server1* to have the IP address of *Attacker*, and thereby sending all packets intended for *Server1* to *Attacker*.

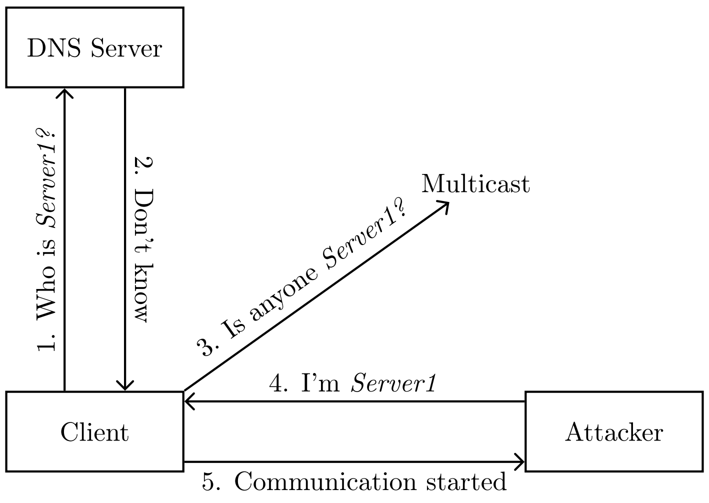

Figure 1: How an attacker spoofs the Name Resolution protocols in order to receive traffic intended for other hosts

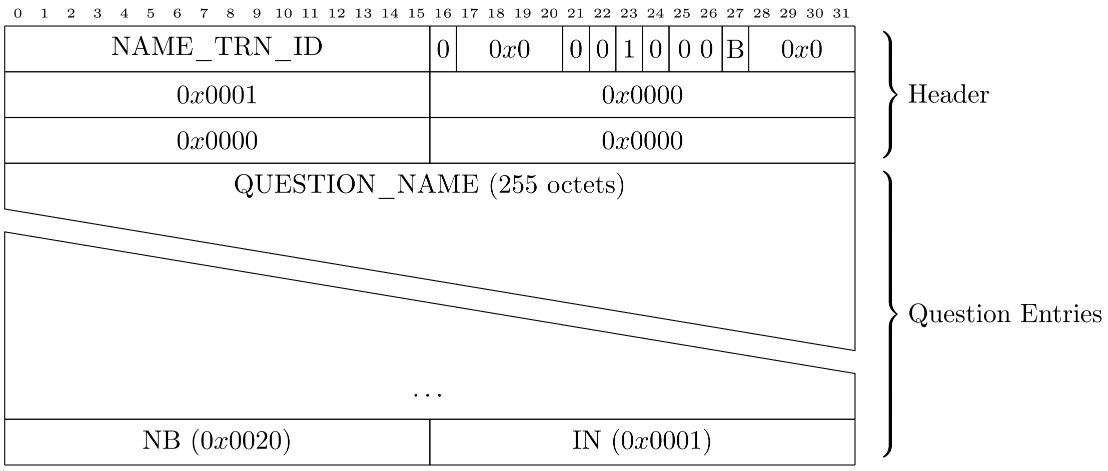
In Windows, two different Name Resolution protocols are used and active by default on all modern Windows versions. LLMNR and NBNS work side by side, unless specifically turned off, which is not the case by default. In section 2.1.2 and 2.1.2 the protocols are analyzed in detail and the attacks are described.
After successfully spoofing a host name and getting traffic redirected to our machine, we need to be able to use that traffic for a malicious purpose. The most common purpose is to gather credentials from the client by having rouge servers running on the attacker. The technique and methods behind this is explained in section 2.2

2.1.1 NetBIOS Name Resolution (NBNS)

In Windows NBNS is implemented in the Windows Internet Name Service (WINS) which is a legacy service used to map host names to IP addresses. In newer versions of Windows it has no use, but it is kept for backward compatibility purposes. The NetBIOS RFC specification, RFC 1001[7], contains much more than Name Resolution, but for spoofing purposes we only need to look at Name Resolution. RFC 1002[8] contains detailed technical specification as to how Name Resolution is implemented in NetBIOS.
NBNS has many other features such as Name Registration, Name Refresh etc. but in order to spoof name resolution we need to understand *Name Query Request* packets and respond with *Name Query Response* packets. The format of a *Name Query Request* is specified on figure 2. As it can be seen, only the fields **NAME_TRN_ID** and **QUESTION_NAME** are necessary to read in order to generate a valid *Name Query Request.*



Where

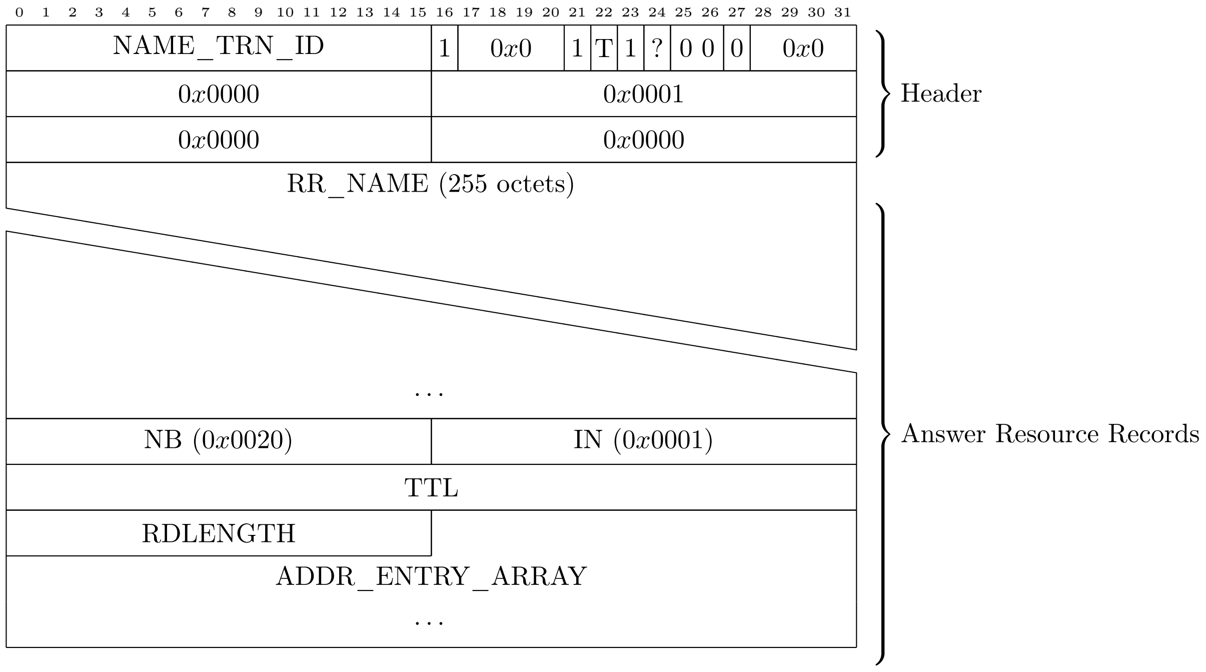
NAME_TRN_ID is the transaction ID for the Name Service Transaction

QUESTION_NAME is the compressed name of the NetBIOS name for the request.

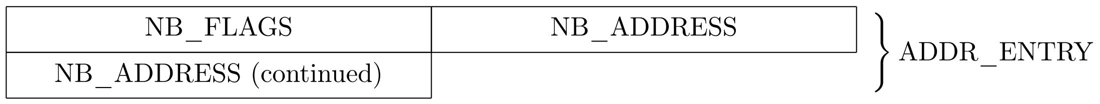
Figure 2: NetBIOS Name Resolution (NBNS) Name Query Request[8, sec. 4.2.12]

To send a spoofed response to the NBNS request we need to reply with a *Name Query Response*. The structure of a response packet can be seen in figure 3. It is important to mention that question name is encoded using a very mysterious encoding and truncated to a maximum of 16 bytes. Each half-byte of the characters ASCII code is added to the ASCII Code 'A'[25], which result in every byte occupying two bytes in the resulting packet. So SERVER1[2] will be encoded to FDEFFCFGEFFCDBCACACACACACACACACA where CA is empty padding until the length is 32 bytes. Figure 3 shows the structure of a response, and describes the values of the different fields.

[2]NetBIOS names are always uppercase



Where each ADDR_ENTRY has the following format:



And

T is whether or not the data is truncated

NAME_TRN_ID is the transaction ID from the request

RR_NAME is the question name from the request

TTL is the time to live for the response in seconds

RDLENGTH is the length of the data field (ADDR_ENTRY_ARRAY)

ADDR_ENTRY_ARRAY is zero or more of the following:

- **NB_FLAGS** consists of three different things. Bit 0 is Group Name Flag (0), bit 1-2 is Owner Node Type (00) and bit 3-15 is reserved for future use (all 0)
- **NB_ADDRESS** is an IP Address. In this case our own IP Address(The IP of the attacker)

Figure 3: NetBIOS Name Resolution (NBNS) Name Query Response[8, sec. 4.2.13]

Figure 4 shows a real request sent from a Windows Server 2016 requesting the host for **Server1**. The corresponding values of **NAME_TRN_ID** and **RR_NAME** is $0xd056$ and FDEFFCFGEFFCDBCACACACACACACACACACA respectively. According to the information gained from figure 3, we need to construct a packet with the specified transaction ID and host name. Additionally, we set **TTL** to $0x000000a5$ (2 minutes and 45 seconds), **RDLENGTH** to 6 ($0x0006$) and NB_ADDRESS to our own IP Address 10.211.55.4 ($0x0ad33704$). This results in the packet seen on figure 5 which is a direct response to 4 leading to a successful spoof.

Figure 5: NBNS Name Query Response

2.1.2 Link-local Multicast Name resolution (LLMNR)

LLMNR is the newest protocol for name resolution where DNS name resolution is not possible[1]. LLMNR works in the same way as NBNS in such that a name query is sent to the link-scope multicast address(es), and a responder can hereafter respond to the packet and claim itself as the host that was requested. The sequence of events with LLMNR according to RFC 4795[1] is the following

1. An LLMNR sender sends a LLMNR query to the link-scope multicast address(es) on port 5355. This is a LLMNR packet containing a Question Section

2. A responder responds to this query by sending an UDP packet. This is a LLMNR packet containing a Question Section and a Resource Record

3. The sender process the responders packet

This is all well if we assume that the network itself is not already compromised. In case a malicious host is existent on the network, and the host is listening on the link-scope multicast address there is nothing from stopping this host in responding maliciously to the packets. LLMNR is made to follow the DNS specification, so in order to spoof it we need to know how DNS packets look like. This can be found in RFC 1035[22].

LLMNR packets There exists two different LLMNR packet types. A **request** and a **response**. The **request** contains the *header* and a *question section.* The **response** contains a *header*, a *question section* and a *resource record.* Format details of these types can be seen in figure 6.

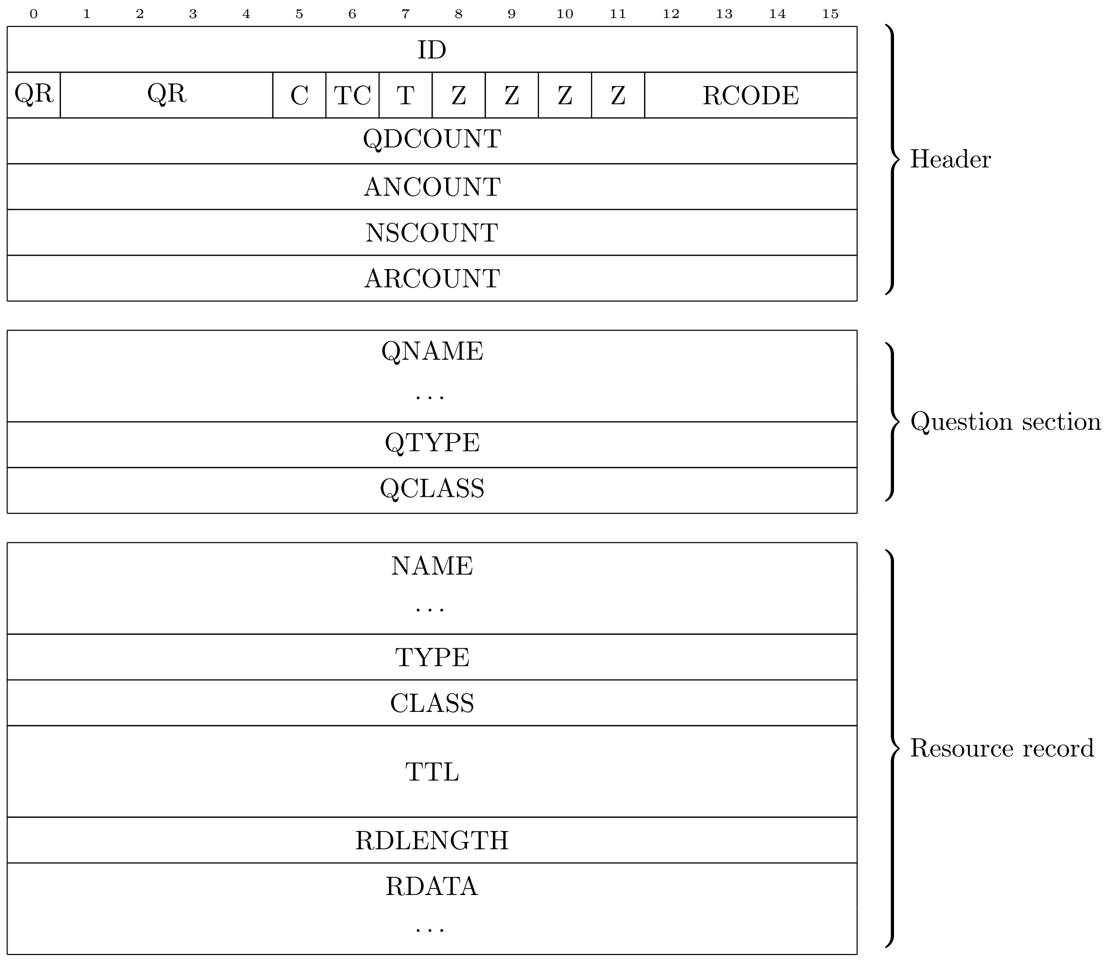

Figure 6: Link-local Multicast Name resolution (LLMNR) packet specification[1][22]

Where

QNAME is a domain name in the following format: A length octet followed by that number of octets

QTYPE is a two octet code which specify the query type. Usually $0x0001$ for Host address(IP)

QCLASS is a two octet code which specify the query class. Usually $0x0001$ for Internet (IN)

And

NAME See QNAME of *Question Section*

Type See TYPE of *Question Section*

CLASS See QCLASS of *Question Section*

TTL is a 32 bit unsigned integer which specify Time To Live in minutes

RDLENGTH is a 32 bit unsigned integer which specify the number of octets in RDATA

RDATA is a variable length string of octets. Usually an IP address

Figure 6: Link-local Multicast Name resolution (LLMNR) packet specification[1][22]

This report will not explain the packet details in full, but will focus on the parts necessary to spoof a LLMNR response.
To answer a LLMNR packet we need to create a *Resource Record* to match the *Question section* sent out by a client. *Name, Type and Class* should match the request, *TTL* should be set to an arbitrary time in minutes (for example 30 - $0x0000001e$ in bytes), *RDLENGTH* should be 4 ($0x0004$) and *RDATA* should be our own IP Address.

```

Figure 8: Spoofed LLMNR response

Figure 7 and 8 shows a valid request and the corresponding spoofed response for a name resolution for *server1*. After responding to the request with the proper response we would have successfully spoofed the LLMNR protocol and redirected traffic intended for server1 to our host(The attacker).

2.2 Credential acquiring

After successfully spoofing either a NBNS or LLMNR request we have now succeeded in imposing as another host, meaning all traffic intended for that host will be directed to us. It is also important to mention that name resolution of non-existing hosts will still be spoofed and therefore be registered by the sender of the request as belonging to us. In Windows, name resolution often happens when trying to request either a Server Message Block (SMB) share or a website using HyperText Transfer Protocol (HTTP). Luckily for us Windows has implemented the Security Support Provider Interface (SSPI) which allows an application to use various security models available on a computer. The security models works as a Single Sign-On (SSO) solution that allows users to easily authenticate to various services using their cached credentials[19]. We can use this to our advantage by implementing a Security Support Provider (SSP) in fake SMB and HTTP services. There exists a couple of different SSP's including Negotiate, NTLM, Kerberos, Digest SSP and others. Microsoft recommends that you use Negotiate as it acts as an application layer between the SSPI and the different SSP's usually choosing Kerberos over NTLM as it is more secure. Though, we can force our service to use the NTLM SSP, which will give us a hash that we can crack offline. The different types of hashes will be discussed in more detail in section 2.2.1.

2.2.1 Credential types

In the windows ecosystem there is a lot on confusion on the different types of hashes and where they are used. This short section aims to describe the different hashes briefly to avoid confusion later on in the project. There exists 4 (or 5 depending on who you ask) different hashes in windows[6]

LM LM is the original hash type used by Windows dating back to OS/2. LM has a number of shortcomings, but the biggest is that it is a maximum length of 14 characters, which is then split into two 7-character chunks, where each part is converted to a DES key and then encrypted with the string "KGS#$%" and concatenated. The obvious flaw here is that you only have to crack two 7-character hashes instead of one, which can easily be done with modern GPUs in mere hours.

NT NT is the current Windows standard for hashing passwords. This is basically just a MD4 of the little endian UTF-16 of the password. MD4 has its obvious flaws concerning collision attacks, but such attacks and methods are out of scope for this project.

NTLM NTLM is a combination of LM and NT hashes in the form *LM:NT*. This hash type can be used in attacks known as pass-the-hash[16] where you can authenticate using the NTLM password instead of the clear-text password. So having the NTLM hash is in most attack scenarios essentially the same as having the clear-text password.

NetNTLMv1 NetNTLMv1 is Microsofts first attempt at a challenge/response hash between a client and a server. It will use either the NT or LM hash to generate the NetNTLMv1 hash. Once again this uses DES and has obvious flaws allowing you to convert it to three different DES keys which can be cracked with much less computer power and converted into an NTLM hash[5].

NetNTLMv2 NetNTLMv2 is the newest challenge/response based hash used for network authentication. This hash uses a 8-byte server and client challenge combined with the current time and domain name to create a more secure hash. It also uses HMAC-MD5 as algorithm, which is more secure than DES. NetNTLMv2 will also use either the NT or LM hash to generate the hash.

2.2.2 NTLM

Besides being a hash, NTLM is also the name of the primary Challenge/Response protocol used in Windows authentication, and can easily be encapsulated in other protocols such as SMB and HTTP. The NTLM authentication protocol consists of three message types and is therefore a simple protocol[14]. The three message types are the following:

Negotiate The client initiates the authentication.

Challenge The servers sends a 16 byte challenge to the client

Authenticate The client encrypts the challenge with the user's hash and sends it to the server.

This is a very simple authentication protocol which has it's obvious flaws. Once you've gotten the encrypted challenge back bruteforcing the password is very trivial. The encrypted challenge returned is either a NetNTLMv1 or NetNTLMv2 hash, as described in section 2.2.1, and can either be converted to a passable hash or bruteforced quickly using a couple of modern Graphics Processing Unit (GPU)'s. All NTLM messages start with the protocol identifier *NTLMSSP* with a null byte (0x00) in the end[23]. After the identifier a type byte (0x01 for negotiate, 0x02 for challenge and 0x03 for authenticate), three null bytes, a four byte flag and another two null bytes. As mentioned, the server sends a **Challenge** message to the client (detailed on figure 9), whereafter the client replies with an **Authenticate** message (detailed on figure 10).

NTLM Challenge Message The Challenge message contains a number of predefined fields such as protocol, flags and zero bytes, and the only not-predefined field is the eight byte challenge that is encrypted with the users password. The challenge is chosen by the server and should, according to the specification, change with every request. But seeing as we are implementing the service ourself, we can choose our own challenge and keep it the same for every request. This is particularly useful for when the password needs to be cracked as we can create rainbow tables beforehand.

0	1	2	3	4	5	6	7
PROTOCOL							
2	0	0	0	0	0	0	0
msg len		0	0	FLAGS		0	0
CHALLENGE							
0	0	0	0	0	0	0	0

Where

PROTOCOL is always *NTLMSSP* followed by a null-byte

CHALLENGE 8 arbitrary bytes chosen by the server

FLAGS always set to $0x8201$

Figure 9: NTLM Challenge message

NTLM Authenticate message The Authenticate message consists of five parts, namely Domain, User, Host, LM and NT. Each part has a length field, which for unknown reasons are duplicated in the protocol, a offset part and the actual content. Each part is separated by two null bits. This can be seen in detail on figure 10. The contents of this message can be combined into an NetNTLMv2 hash with the format *User::Domain:Challenge:LM:NT*

0	1	2	3	4	5	6	7

DOMAIN …							
USER …							
HOST …							
LM …							
NT …							

Where

PROTOCOL is always *NTLMSSP* followed by a null-byte

CHALLENGE is 8 arbitrary bytes chosen by the server

Figure 10: NTLM Authenticate message

2.2.3 Server Message Block (SMB)

As stated in section 2.2 we need to implement a NTLM SSP in SMB. In SMB this is done by encapsulating the NTLM authentication into SMB. A SMB session is first started whereafter NTLM authentication happens and then the SMB session is continued. For this project we do not need to implement the full SMB protocol, as we are only interested in the NTLM authentication and the encrypted challenge we get hereof. The full flow of this process can be seen on figure 11 which starts after a host has successfully been spoofed to redirect traffic to our host.

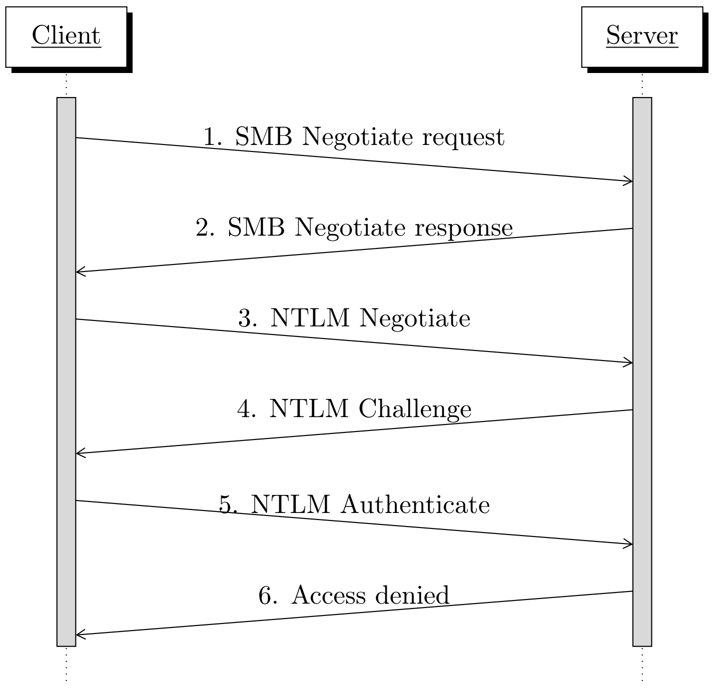

Figure 11: SMB NTLM authentication[17]

The authentication flow of SMB, which can be seen on figure 11, uses the following messages in the mentioned order

1. SMB_COM_NEGOTIATE The client first sends a SMB_COM_NEGOTIATE message to negotiate the supported authentication types.

2. SMB_COM_RESPONSE The server responds with a SMB_COM_REPONSE stating the used authentication method that both the client and server supported. In our case this will always be set to NTLM authentication as we are not interested in Kerberos authentication, or any other authentication for that matter.

3. SMB_COM_SESSION_SETUP_ANDX request 1 The client sends an encapsulated NTLM Negotiate message to the server.

4. SMB_COM_SESSION_SETUP_ANDX response 1 The server receives the NTLM negotiate message and replies with a NTLM Challenge

5. SMB_COM_SESSION_SETUP_ANDX request 2 The client sends a NTLM Authenticate message containing the encrypted challenge

6. Access denied An access denied response is sent to close the connection to the client. At this point we will have received a NetNTLMv1 or NetNTLMv2 hash, so we don't wish to continue the session.

In step **(5)** we receive an *NTLM Authenticate* message which contains the encrypted challenge. An example of such a message can be seen on figure 12. Using the data given in this message, we can construct a NetNTLMv2 password hash which can be cracked offline using various cracking techniques such as bruteforcing or rainbow tables.

Figure 12: SMB NTLM Authenticate Message

2.2.4 HyperText Transfer Protocol (HTTP)

Implementing a NTLM HTTP SSP is, once again, done by encapsulating the NTLM authentication messages into HTTP. This is done using the headers **WWW-Authenticate** and **Authorization** for the server and client respectively. The flow is very similar to that of SMB, and can be seen on figure 13. The flow starts with a client accessing a server on the standard HTTP port 80[3], with the server responding with a 401 Unauthorized and supplying the header *WWW-Authenticate: NTLM* to let the client know that the server supports NTLM authentication. After this the standard NTLM authentication occurs with Negotiate, Challenge and Authenticate messages encapsulated in HTTP. One important point to highlight is that the NTLM messages are encoded using base64 as HTTP is a text based protocol. After a successful NTLM Authentication over HTTP we are once again left with a Authenticate message containing the necessary information to construct a NetNTLMv2 password hash that can be cracked offline using various techniques.

[3]In theory this can be any arbitrary port but seeing as we're obtaining data based on spoofing we need to listen on port 80

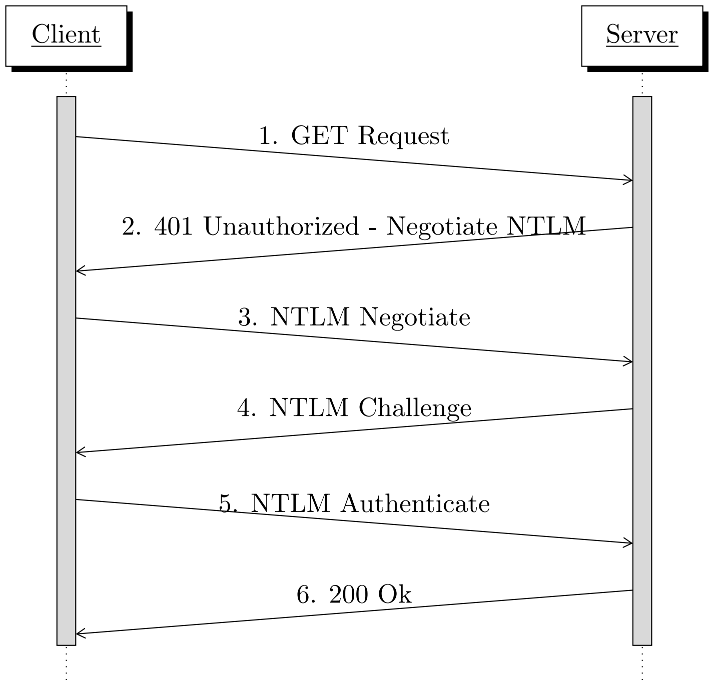

Figure 13: HTTP NTLM authentication[23]

1. GET Request The client initiates the connection with a GET request to the server

2. 401 Unauthorized The server responds the GET requests with a 401 Unauthorized response containing the HTTP header *WWW-Authenticate: NTLM* letting the client know that it should authenticate using NTLM

3. NTLM Negotiate The client responds with another GET request containing the base64 encoded NTLM Negotiate message encapsulated in the Authorization header

4. NTLM Challenge The server responds with the base64 encoded NTLM Challenge message containing the challenge the client should encrypt in the WWW-Authentication header

5. NTLM Authenticate The client responds with the base64 encoded NTLM Authenticate message

6. 200 Ok The server now responds with a 200 Ok which let the client know that the credentials were accepted.

The methods has been tested on all major browser (Internet Explorer, Chrome, Firefox and Edge), and works flawlessly in all of them.

3 Attack methods

After successfully spoofing a victim by abusing LLMNR and NBNS and getting a NetNTLMv2 hash by running fake SMB and HTTP services, we are at a point where we need to use more traditional methods to compromise the network further. As mentioned in section 2.2.1 both NetNTLMv2 and NetNTLMv1 hashes encrypts the server given challenge with either the NT or LM hash. In other words we can use bruteforcing tools such as hashcat[9] to crack the hashes and gain the original password, which will of course lead to a full user compromise as we then have username and password in clear-text.
In the rare case that a password is sufficiently complex and cannot easily be cracked or otherwise guessed, there still exists methods to utilize spoofing and poisoning to gain unauthorized access to systems. One such method is called NTLM Relaying[2] where you construct your HTTP or SMB services to relay the credentials to another server/host.[4]
After having cracked the password we need to move on to compromising the domain further. There are many was of doing this, and it it very dependent on the targets of the pentest. A common target for many Windows pentests is to gain Domain Admin privileges, either by compromising a user already possessing the privilege or by exploiting various vulnerabilities. This project's primary goal is to become Domain Admin in a quiet and efficient way that does not disturb the network, and remain as close to undetectable as possible. Using vulnerabilities is first and foremost a very uncertain way of achieving Domain Admin privileges, as most known vulnerabilities are fixed quite easily and we are not in the position of possessing zero day vulnerabilities for Windows. Luckily there are many other methods to achieve lateral movement in a Windows domain, which this project will explore further in the following sections. Analyzing and discussing all the different types of attack would in itself be a very big project, so in this report we will focus on Local Security Authority Subsystem Service (LSASS) that, among other things, handles storage of credentials.

3.1 Local Security Authority Subsystem Service (LSASS)

LSASS is a protected subsystem that handles authentication and sessions in Windows. So whenever an user login to a Windows machine, access it via Remote Desktop Protocol (RDP) or connect using SMB LSASS will handle the authentication and store the credentials in a safe way afterwards[5]. The feature of storing password in the memory is actually what SSO uses to sign-in

[4]Relaying credentials is outside the scope of this project, but is something that would work well with the rest of setup

[5]LSASS does not always save the credentials in memory, it depends on the type of authentication and how it happens[18]

automatically to services, and it is a very essential part of why spoofing certain protocols work. But, it also gives us other opportunities to steal credentials. After gaining access to one user, using the aforementioned mentioned methods, we are freely available to query information in the Active Directory (AD) which can give us information about hosts, user privileges, user groups etc. Using this information it is possible to find hosts where the compromised user has administrator privileges. These privileges can be used to create a remote connection to the host and steal sessions from that particular host. Lets for example say that User1 has administrator privileges on the host jumpserver1. On jumpserver1 three other users are authenticated using RDP and currently have an active session. In this case the LSASS process (lsass.exe) on the host jumpserver1 will therefore contain a total of four cached credentials in the process memory. The type of password hash stored in memory varies with different Windows systems and level of patching, but a generel rule of thumb is that servers after Windows Server 2008 R1 and clients after Windows 7 mainly saves the password as a NT hash, and hosts before the mentioned versions save it as clear-text[20]. Of course there exists tool to extract these credentials given an interactive login or a memory dump of the LSASS process. This will be discussed in depth in section 3.2.1.

Using this knowledge we clearly see a way of performing lateral movement through the network, and in most cases this will eventually lead to an account with Domain Admin privileges. Although we cannot be sure that the passwords we compromise through LSASS memory dumps are clear-text, this will not pose a problem as explained in section 3.2

3.2 Remote access

Remote access should be understood in the sense of getting an interactive session on another host, where the session can be used to interact with this host using either a command line or graphical interface. In Windows there are many official and unofficial ways to achieve this. Among official ways you will find methods such as **Enter-PSSession**, **Invoke-Command**, **PSExec**, **Windows Remote Management (WINRS)**, **RDP** and **Windows Management Instrumentation (WMI)**. These all work very well when you have valid credentials with clear-text passwords. But as stated in section 3.1 dumping credentials from LSASS memory will, in newer versions of Windows, give you a NT hash and not the clear-text password. In these cases we can utilize a technique called Pass-the-hash (PTH), which will allow us to use NTLM Authentication to authenticate against a remote host using a hashed password.

Pass-the-hash (PTH) Pass-the-hash (PTH) attacks is a way of authenticating to a remote host using a NT or LM hash instead of of the clear-text password. If we look closer at the "NTLM Authenticate message" figure from page 17 and the NetNTLMv2 hash from section 2.2.1, we can clearly see that the NetNTLMv2 hash is based on the NT or LM hash and **not** the clear-text password. Even though Windows default to Kerberos authentication, we can

still force the host to accept NTLM Authentication unless it is actively disabled. Though, even with Kerberos authentication we can still use the NT or LM hash to create a ticket which can then be passed, but that is outside the scope of this project and has other implications as it requires direct communication with a Key Distribution Center (KDC)[6].
PTH attacks can be used with most Windows protocols such as SMB and WMI, but it requires you to re-implement the protocol to be able to use it, as Windows did not make the feature available in any of their official tools. Luckily the Impacket project has done most of the work already. As it states in their description, *"Impacket is focused on providing low-level programmatic access to the packets and for some protocols (e.g. SMB1-3 and MSRPC) the protocol implementation itself."*[10].
From common usage of the Impacket library and the accompanying tools in the Impacket suite, the author has had best result with the WMIExec tool for remote access, and therefore that is the one used in this project.

Impacket WMIExec WMIExec is a remote access tool from the Impacket suite that supports both clear-text and PTH authentication. Furthermore it has a semi-interactive shell accompanied, which can be used to upload and download files to/from the remote host. If we look deeper into the technical process, it works by using WMI to execute commands and SMB to upload/download files. Looking at the source code[11] we can get an overview of how it works.

1. A SMB connection is established to the remote host using NTLM Authentication. This SMB connection is used every time a file needs to be uploaded or downloaded
2. If the command parameter is not set, the tool will do nothing and wait for input, otherwise it will use the WMI protocol to execute a command and get the result
3. In the case that an interactive shell is started, the tool will execute every command inputted by executing a remote command using the WMI protocol, and thereafter return the result when the remote command has executed

Now that we have a remote access to the host using either clear-text credentials or a hash, we can start the process of extracting memory from the LSASS process. As mentioned in section 3.1, this process will contain all credentials for currently active sessions.

Dumping LSASS memory Dumping memory of a process in Windows is a somewhat difficult tasks when you do not have a graphical interface. Using a graphical interface you can easily dump the memory of a process using Task Manager[13], but having only access to the command line it is somewhat more

[6] In Windows this is usually a DC

difficult as no native ways exists. One solution is to use the tool Procdump from Microsoft's Sysinternal toolset.
With a WMIExec connection present we can do the following to dump and download the memory of the LSASS process a remote host

1. Start WMIExec with a remote connection to the remote host
2. Upload the Procdump tools to the remote host
3. Run Procdump with the parameters *-ma -accepteula lsass.exe debug.dmp* to save the LSASS process memory to debug.dmp
4. Download the debug.dmp file to our own machine
5. Delete Procdump and debug.dmp
6. Close the connection

3.2.1 Local Security Authority Subsystem Service (LSASS) memory credential extraction

The LSASS process is a complex process with many usages as mentioned in section 3.1. The part we are interested in for this project is the credentials stored in memory. A lot of effort has gone into reverse engineering and studying the memory of this process, but the most interesting work has been done by Benjamin Delpy who created the very well known tool Mimikatz[3].

Mimikatz Mimikatz has a lot of features but is mostly known for being able to extract credentials from the memory of Windows machines. Over the years many steps have been taken to make Mimikatz irrelevant, but it continues to be one of the most useful tools for Windows hacking. Mimikatz can work on both memory dumps or directly on the host, and in this project we are interested in working on a memory dump, as uploading Mimikatz to a host will in many cases be flagged by AV. For this project we are therefore mostly interested in the following commands from the sekurlsa[7] module[4]

sekurlsa::minidump The minidump command will switch Mimikatz into working on a memory dump instead of the current machine

sekurlsa::logonpasswords The logonpasswords will extract all credentials found in memory. This may include both clear-text and hashed passwords

One important note is that in order for Mimikatz to work properly on a memory dump, the architecture of the hosts must match, so that if the memory dump is from a x64 machine the host doing the credential extraction must also be a x64 machine.

[7]sekurlsa means Secure Local Security Authority (LSA)
